(Received 3 December 2012; accepted 27 January 2014)

In this paper, we propose a hybrid modelling and control design scheme for an unmanned helicopter. This control structure has a hierarchical form with three layers: the regulation layer, the motion planning layer, and the supervision layer. For each layer, a separate hybrid controller has been developed. Then, a composition operator is adopted to capture the interactions between these layers. The resulting closed-loop system can flexibly command the helicopter to perform different tasks, autonomously. The designed controller is embedded in the avionic system of an unmanned helicopter, and actual flight test results are presented to demonstrate the effectiveness of the proposed control structure.

Keywords: hybrid modelling and control theory; hierarchical control; unmanned aerial vehicles; flight control

1. Introduction

Recent years have seen an increasing research interest in unmanned helicopters due to their wide range of applications. Compared with fixed-wing airplanes, helicopters have advantages such as vertical taking-off/landing and capability of hovering, which makes them more suitable to fly in urban areas. However, the flight control of an unmanned helicopter is highly non-trivial and involves several technical and theoretical challenges (Ollero & Merino, 2004). Therefore, we are interested in building a control architecture that is tractable for theoretical analysis and meanwhile flexible enough to enable an unmanned aerial vehicle (UAV) to perform different missions autonomously. A typical mission is composed of several tasks for which separate controllers are required to be designed. Then, a decision-making unit needs to be embedded to coordinate the controllers based on assigned tasks. Hence, the control structure of a UAV has a hybrid nature, which includes both continuous and discrete dynamics that interactively coexist in the system (Sobh & Benhabib, 1997). It is common to treat the discrete and continuous dynamics of the UAVs in a decoupled way (Dong, Chen, Cai, & Peng, 2007; Fatemi, Millan, Stevenson, Yu, & O’Young, 2008), which simplifies the design procedure. However, the ignorance of the discrete dynamics and its coupling effect on the continuous dynamics of the system is questionable and may degrade the reliability of the system (Karimoddini, Lin, Chen, & Lee, 2009).

To address these challenges, one solution is to use hybrid modelling and control theory to uniformly model and handle both discrete and continuous dynamics of the system (Antsaklis & Nerode, 1998). To explore the applications of hybrid modelling and control theory in the sophisticated structures of UAVs, in Bayraktar, Fainekos, and Pappas (2004), a hybrid controller is developed for the control of the altitude and turning rate of a fixed-wing UAV. For quadrotors, in Gillula, Huang, Vitus, and Tomlin (2010), a hybrid model for the backflip manoeuvring is provided for which a forward reachability analysis guarantees the switching sequence for correct execution of the task. Similarly, in Naldi, Marconi, and Gentili (2009), a robust reachability analysis is given for taking-off and landing of a ducted-fan aerial vehicle. When the vehicle is landing, upon contacting with the ground, the control dynamics will be changed. So, the hybrid controller pushes the switching sequence to safely land on the ground. In Frazzoli, Dahleh, and Feron (2000), the path planning of a UAV helicopter is translated to a robust hybrid analysis problem and the results are verified through simulation, and in Schouwenaars, Mettler, Feron, and How (2003), a hybrid controller for the velocity control of a helicopter is provided where mixed integer linear programming (MILP) is used for the optimal reference generation. In contrast, in this paper, instead of focusing on a specific task, our aim is to propose a framework for the hybrid control of a UAV helicopter so that it can autonomously accomplish the assigned mission. To reduce the complexity of the system and to facilitate the design procedure, we have developed a hierarchical control structure in a systematic way to distribute the control tasks among the layers. The use of hierarchical control and its application to coordination problems have been studied for a long time (Findeisen
et al., 1980; Mesarović, Macko, & Takahara, 1970); however, considering the concept of hierarchical control within hybrid framework still is a challenging problem.

Hence, the contribution of this paper is that first we have proposed a formal hierarchical hybrid modelling and control approach for UAV systems. The proposed control system has three layers: the regulation layer, which is responsible for the low-level control; the motion planning layer, which is responsible for path generation to be followed by the regulation layer; and the supervision layer, which is the decision-making unit and is responsible for managing the switching scenario to perform a mission autonomously. Each layer has been modelled with an input/output hybrid automaton (Lynch, Segala, & Vaandrager, 2003). Then, we have introduced a composition operator to synchronise the layers and capture the interplay between them. The existing definitions of composition operators either are only useful for fully connected systems (Johansson, 2005), or cannot refine the discrete transitions or states of the system (Lynch, Segala, & Vaandrager, 2001; Rashid & Lygeros, 1999). In contrast, in this paper, a new composition operator is proposed that is able to be used for partially connected systems and can refine the discrete transitions and states in an efficient way.

Finally, the designed controller is implemented on the NUS UAV helicopter (Peng et al., 2009), and real flight tests are conducted to evaluate the proposed hybrid control structure. The flight test results show that the designed control system can be effectively involved in a complex mission composed of several tasks.

The remaining parts of this paper are organised as follows. First, in Section 2, the model of the NUS UAV helicopter is described to be used in our further derivations. Then, in Section 3, a hierarchical hybrid framework has been developed for this UAV helicopter and the layers of this hierarchy are discussed in detail. The experimental results are presented in Section 4, and finally, the paper is concluded in Section 5.

2. The UAV model and structure

Before developing a hybrid controller for a UAV helicopter, its model and structure are briefly explained in this section. Here, the test-bed is the NUS UAV helicopter (Figure 1), which is developed by our research group in the National University of Singapore. This helicopter is a Raptor-90 helicopter, which is equipped with an avionic system, including the onboard computer system, the sensors, and the actuators that together generate the control signals for an automatic flight. The construction procedure of such an autonomous UAV is described in Cai, Feng, Chen, and Lee (2008), the hardware details are explained in Cai, Peng, Chen, and Lee (2005), and its low-level flight control performance is discussed in Peng et al. (2009).

Based on the first-principle modelling approach detailed in Cai, Chen, Lee, and Lum (2008), a nonlinear dynamic model for the NUS UAV helicopter has been obtained, which is highly accurate in a wide range of flight envelope. Using the trust-region dogleg method, the obtained model then has been linearised at the hovering state in which the linear and angular velocities, the pitch angle, and the roll angle of the UAV are close to zero (Cai, Chen, Peng, Dong, & Lee, 2006). To capture the UAV dynamics, it is required to consider two coordinate systems. The moment and force equations must be derived in a moving coordinate system whose origin is located at the centre of gravity of the UAV, whereas to obtain the net displacement of the UAV, we need to consider a fixed coordinate system that is centred in the flight starting point. The moving and fixed coordinate systems are called the body frame and the ground frame, respectively.

Deriving the force and moment equations in the body frame of the UAV and linearising the resulting nonlinear model at the hovering state will result in the following model:

$$\dot{x}_m = Ax_m + Bu,$$

where $x_m = [V_x \ (m/s) \ V_y \ (m/s) \ \omega_z \ (rad/s) \ \omega_y \ (m/s) \ \phi (rad) \ \theta (rad) \ \tilde{\omega}_1 (rad) \ \tilde{\omega}_2 (rad) \ V_x \ (m/s) \ \omega_z \ (rad/s) \ w_{zf} \ (rad/s)]'$ is the internal state of the system. Here, $V_x, V_y,$ and $\omega_z$ are the linear velocities; $\omega_x, \omega_y,$ and $\omega_z$ are the angular velocities; $\phi$ is the roll angle; $\theta$ is the pitch angle; $\tilde{\omega}_1$ and $\tilde{\omega}_2$ are the flapping angles, and $w_{zf}$ is the state variable of the gyro rate that introduces a first-order differential equation to capture the effect of $\delta_{pedal}$ (Peng, Cai, Chen, Dong, & Lee, 2006). Furthermore, $u = [\delta_{roll} \ (rad) \ \delta_{pitch} \ (rad) \ \delta_{pedal} \ (rad)]'$ is the vector of the control input signals, to be given to the servos to control the angle of the blades and to drive the UAV in different directions. Finally, $w = [u_{wind}, v_{wind}, w_{wind}]$ is the wind gust disturbance where $u_{wind}, v_{wind}, w_{wind}$ affect the UAV velocities in the $x$-, $y$-, and $z$-directions, respectively. The state and input matrices $A$ and $B$ of the corresponding linearised
model, and the disturbance matrix \( E \) are as follows:

\[
A = \begin{bmatrix} A_2 & 0_{8 \times 3} \\ 0_{3 \times 8} & A_1 \end{bmatrix}, \quad B = \begin{bmatrix} B_2 & 0_{8 \times 2} \\ 0_{3 \times 2} & B_1 \end{bmatrix},
\]

\[
E = \begin{bmatrix} E_2 & 0_{8 \times 1} \\ 0_{3 \times 1} & E_1 \end{bmatrix},
\]

where

\[
A_1 = \begin{bmatrix} -0.6821 & -0.1070 & 0 \\ -0.1446 & -5.5561 & -36.6740 \\ 0 & 2.7492 & -11.120 \end{bmatrix},
\]

\[
B_1 = \begin{bmatrix} 15.6491 \\ 1.6349 \\ 0.0496 \end{bmatrix}, \quad E_1 = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix},
\]

\[
B_2 = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ -0.1778 & -0.3104 \\ -0.3326 & -0.2051 \\ 0.0802 & -0.2940 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ -0.1903 & -0.2940 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix},
\]

\[
E_2 = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix},
\]

\[
A_2 = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ -9.7807 & -9.7808 & 0 \\ 9.7807 & 0 & 0 & 9.7807 \\ 0 & 0 & 75.7640 & 343.86 \\ 0 & 0 & 172.620 & -59.958 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & -8.1222 & 4.6535 \\ 0 & 0 & -0.0921 & -8.1222 \end{bmatrix}.
\]

To obtain the net displacement of the UAV, \( x_{\text{out}} \), we should first obtain the velocity vector in the ground frame as a fixed coordinate system, and then, the integration of the velocity vector in the fixed frame will yield the net displacement:

\[
\dot{x}_{\text{out}} = \Omega(\Theta)C x_{\text{in}},
\]

where \( x_{\text{in}} = [x \ (\text{m}) \ y \ (\text{m}) \ z \ (\text{m}) \ \psi \ (\text{rad})]^T \). Here, \( x, y, \) and \( z \) describe the position of the UAV in the ground frame, \( \psi \) is its heading, and \( \Theta = [\phi, \theta, \psi]^T \) is the orientation vector. Matrix \( C \) and the block \( \Omega(\Theta) \) are as follows:

\[
C = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}, \quad \Omega(\Theta) = \begin{bmatrix} R(\Theta) & 0 \\ 0 & 1 \end{bmatrix},
\]

where the block \( R(\Theta) \) is a transformation matrix from the ground frame to the body frame and it has the following form:

\[
R(\Theta) = \begin{bmatrix} \cos \theta \cos \psi & \sin \phi \sin \psi + \sin \phi \sin \theta \cos \psi & \cos \theta \sin \psi \\ -\cos \phi \sin \psi + \sin \phi \sin \theta \cos \psi & \sin \phi \cos \psi + \cos \phi \sin \theta \cos \psi & \cos \phi \cos \psi \\ \cos \phi \cos \psi & \cos \phi \sin \theta \sin \psi + \sin \theta \cos \phi \cos \theta & \cos \phi \cos \theta \end{bmatrix}.
\]

The model diagram of the UAV helicopter is depicted in Figure 2. In the next section, we will discuss about the control design for this semi-linearised model of the UAV within the hybrid modelling and control framework.

3. Hybrid modelling and control of an unmanned helicopter

3.1 Hierarchical hybrid modelling and control of an unmanned helicopter

To design a fully autonomous controller for this helicopter, we propose a hierarchical hybrid control structure that consists of three layers: the regulation layer, the motion planning layer, and the supervision layer. Each layer has a hybrid structure and is responsible to do a specific task. The relation between these layers can be described by hybrid composition operator. Figure 3 shows the overall picture of this system and describes the nature and objectives of each layer. The philosophy behind this hierarchy is that the lower levels are involved in more details such as reference tracking and stability analysis, while the higher levels mostly manage and coordinate the control scenarios to achieve the assigned task. The advantage of this structure is that it simplifies the design procedure so that each layer can be developed to accomplish a particular part of the control task. Next, we will describe the layers of this control hierarchy.
3.2 The regulation layer

The regulation layer is directly connected to the UAV avionic system and can manipulate the actuators and gather the sensors reading for the control process. It also receives the task scheduling commands from the motion planning layer to activate proper control modes. For different velocities and situations, different controllers can be designed. For example, in Cai, Chen, Dong, and Lee (2010), several controllers have been designed for different modes of operation of the NUS UAV helicopter. Then, the higher layers are responsible to activate the proper control modes. To elaborate the idea of hierarchical control, without loss of generality, here we consider two control modes for the regulation layer of this UAV as described in the following parts.

3.2.1 Velocity control mode

In the velocity control mode (vc), one can stabilise the attitude of the helicopter and control the UAV to move with the desired velocity vector \( (v_x, v_y, v_z) \) and the desired yaw rate, \( \omega_z \). For this purpose, we will use an \( H_\infty \) controller by which both the robust stability and a proper performance of the system can be achieved, simultaneously. To design a \( H_\infty \) controller, first, looking at matrices \( A, B, \) and \( E \) in Equation (1), it can be seen that the model is a decoupled system with two separate subsystems as follows:

\[
\begin{align*}
\dot{x}_1 &= A_1 x_1 + B_1 u_1 + E_1 w_1, \\
\dot{x}_2 &= A_2 x_2 + B_2 u_2 + E_2 w_2,
\end{align*}
\]

where \( x_1 = [V_{z_b} \text{ (m/s)} \ \omega_{z_b} \text{ (rad/s)} \ \omega_{z_f} \text{ (rad/s)}] \), \( u_1 = [\delta_{\text{col}} \ \delta_{\text{pedal}}]^T \), \( x_2 = [V_{x_b} \text{ (m/s)} \ V_{y_b} \text{ (m/s)} \ \omega_{x_b} \text{ (rad/s)} \ \omega_{y_b} \text{ (rad/s)} \ \phi \text{ (rad)} \ \theta \text{ (rad)} \ \phi_i \text{ (rad)} \ \theta_i \text{ (rad)}]^T \), and \( u_2 = [\delta_{\text{nol}} \ (\text{rad}) \ \delta_{\text{pitch}} \ (\text{rad})]^T \).

Now, starting with subsystem 1, and using the notation analogous with Chen (2000), we define the measurement output simply as the state feedback in the form of \( y_1 = C_{11} x_1 \) with \( C_{11} = I \). Also, we define the controlled output \( h_1 \) in the form of \( h_1 = C_{12} x_1 + D_{12} u_1 \), where

\[
C_{12} = \begin{bmatrix} 0_{2 \times 3} \\ 3.1623 & 0 & 0 \\ 0 & 3.1623 & 0 \\ 0 & 0 & 1.7321 \end{bmatrix},
\]

\[
D_{12} = \begin{bmatrix} 44.7214 & 0 \\ 0 & 28.2843 \\ 0_{3 \times 2} \end{bmatrix}.
\]

The non-zero entries of \( C_{12} \) and \( D_{12} \) are used for tuning the controller. Here, they are determined experimentally to achieve the desired performance. Meanwhile, the \( H_\infty \) design guarantees internal stability and robustness of the system. Indeed, \( H_\infty \) control design reduces the effect of the wind gust disturbance on the control performance, by minimising the \( H_\infty \) norm of the closed-loop transfer matrix from the disturbance \( w \) to the controlled output \( h_1 \), denoted by \( T_1 \). The \( H_\infty \) norm of the transfer function \( T_1 \) is defined as follows:

\[
\|T_1\|_\infty = \sup_{\omega \in \mathbb{C}} \sigma_{\text{max}}[T_1(j\omega)],
\]

where \( \sigma_{\text{max}}[*] \) denotes the maximum singular value of the matrix *.

Having the matrices \( C_{12} \) and \( D_{12} \), one can find \( \gamma_* \), which is the optimal \( H_\infty \) performance for the closed-loop system from the disturbance input \( w \) to the controlled output \( h_1 \) over all the possible controllers that internally stabilise the system. As practically \( \gamma_* \) is not achievable, we will try to reach \( \gamma_* \), which is slightly larger than \( \gamma_* \).

With this choice of the control parameters, \( D_{11} \) and \( D_{12} \) are full rank and the quadruples \( (A_1, B_1, C_{12}, D_{12}) \) and \( (A_1, E_1, C_{11}, D_{11}) \) are left invertible and are free of invariant zeros. Therefore, we have a so-called regular problem, for which we can use the well-established \( H_\infty \) control theory (Chen, 2000). As it was mentioned, the resulting closed-loop system suboptimality minimises the \( H_\infty \) norm of the transfer function from the disturbance \( w \) to the controlled output \( h_1 \). As a result, \( F_1 \) is the \( H_\infty \) control gain that can be achieved as follows:

\[
F_1 = -(D_{12} C_{12})^{-1}(D_{12} C_{12} + B_1 P_1),
\]

where matrix \( P_1 \) is the positive semi-definite solution of the following \( H_\infty \) algebraic Riccati equation:

\[
A_1' P_1 + P_1 A_1 + C_{12}' C_{12} + P_1 E_1 E_1' P_1 / \gamma^2 - \delta P_1 B_1 + C_{12}' D_{12}(D_{12}' C_{12} + B_1' P_1) = 0.
\]
smoothly drives the U A V to the desired position
velocity control mode. The outer-loop controller, however,
to drive the U A V to follow the desired path. In other words,
and its parameters,
The inner-loop controller stabilises the attitude of the U A V,
consists of two layers: the inner loop and the outer loop.

Figures 4 and 5 illustrate the controllers for the position
and velocity control of the U A V, respectively.

will lead to \( F_1 = \begin{bmatrix} -0.0935 & -0.005 & 0.0027 \\ 0.0008 & 0.0364 & -0.0481 \end{bmatrix} \). The
same procedure can be followed for subsystem 2, and the resulting feedback gain will be \( F_2 = \begin{bmatrix} 0.0017 & -0.1683 & -0.0846 \\ 0.0081 & -1.9336 & -0.1974 & -0.3277 & -2.1444 \\ 0.0815 & -0.0461 & -0.0087 & -0.0535 & -0.3908 & -1.0690 & -1.1712 & -0.4659 \end{bmatrix} \).

Then, considering these two subsystems together, the con-

H∞ design technique, \( G = -(C(A + BF)^{-1}B)^{-1} \) is the
feedforward gain, obtained from the inverse of the system
steady-state gain, and \( r = (V_x, V_y, V_z, V_w) \) includes the
linear and heading velocity references.

3.2.2 Position control mode

The control objective in the position control mode \((pc)\) is
to drive the U A V to follow the desired path. In other words,
the state variable \( x_{out} \) should track the given reference \( r \).
The control law for this operation mode is \( u = F x_{in} + G \Omega K_p (r - x_{out}) \). As it is shown in Figure 5, this controller
consists of two layers: the inner loop and the outer loop.
The inner-loop controller stabilises the attitude of the U A V,
and its parameters, \( F \) and \( G \), are selected as the same as
the velocity control mode. The outer-loop controller, however,
smoothly drives the U A V to the desired position \( r = (x, y, z, \psi) \). In the outer loop, the block \( \Omega \) is used to compensate
for the transformation matrix \( \Omega' \), as they have the property
that \( \Omega \Omega' = I \), and \( K_p \) is a P-controller. In Karimoddini,
Cai, Chen, Lin, and Lee (2010), a tractable procedure has
been proposed for the design of a decentralised P-controller,
\( K_p \), for multi-variable systems, based on the generalised
Nyquist theorem and disturbance analysis.

3.2.3 Hybrid model of the regulation layer

Now, we can present the hybrid model of the regulation
layer based on what explained for each control mode. Both
control modes have the same plant dynamics \( \dot{x}_{in} = A x_{in} + B u \); however, the control law in the velocity control mode
is \( u = F x_{in} + G \Omega K_p (r - x_{out}) \).

The graph representation of the hybrid model of the
regulation layer is shown in Figure 6. Formally, this
hybrid model of the regulation layer can be described by a
hybrid automaton (Liu et al., 1999; Lynch et al., 2003),
\( H_R = (V_R, X_R, U_R, Y_R, \text{start, inv, init, invr, en, guarded, resets, hr}) \), where

- \( V_R = \{ \text{start, vc, pc} \} \) is the set of discrete states, where \( vc \) and \( pc \) stand for the velocity control mode and the
position control mode, respectively. The \text{start} mode
is used for the initialisation of the system to choose
either of the modes.
- \( X_R = [x_{in}, x_{out}] \) is the continuous state of the
system.

Figure 6. The hybrid model for the regulation layer.
\( U_R = U_{D_R} \times U_{C_R} \) is the input space, where \( U_{C_R} = r \subseteq \mathbb{R}^d \) is the continuous control input, and \( U_{D_R} = \{ \text{cmd}_v, \text{cmd}_P \} \) is the set of discrete inputs. The subscripts denote the corresponding ending discrete states in Figure 6. For instance, \( \text{cmd}_P \) is the command that fires a transition to the position control mode.

- \( Y_R = Y_{D_R} \times Y_{C_R} \) is the system output, where here, \( Y_{C_R} = x_{\text{out}} \) and \( Y_{D_R} = V_R \) feedback the current state of the system to the motion planning layer to be able to generate appropriate reference signals.

- \( f_R : V_R \times X_R \times U_R \rightarrow X_R \) is the vector field description of the system that is defined as follows:

\[
\dot{x} = f_R(v, x, u) = \begin{cases} 0 & \text{if } v = \text{start} \\ \left((A + BF)x_u + BGr \right) & \text{if } v = \text{vc} \\ \left((A + BF)x_u - B GGK_x u + B GGK_p r \right) & \text{if } v = \text{pc} \end{cases}
\]

- \( \text{Init}_R = \{ (\text{start}, 0) \} \subseteq V_R \times X_R \) is the set of initial states of the UAV.

- \( \text{Inv}_R \subseteq V_R \times X_R \times U_R \) is the invariant condition. Here, it is required that for both discrete modes, \( z > 0 \), \( v_x, v_y, v_z < 3.5 \text{ m/s}, \omega_x < 15 \text{ deg/s} \) and \( a, b, \theta, \phi < \frac{\pi}{2} \).

- \( E_R \subseteq V_R \times X_R \) is the set of discrete transitions. Here, \( E = \{ (\text{start}, \text{vc}), (\text{start}, \text{pc}), (\text{pc}, \text{vc}), (\text{vc}, \text{pc}) \} \).

- \( \text{Guard}_R : E_R \rightarrow 2^{X_R \times U_R} \) describes the guard conditions for the discrete transitions. For each discrete transition from the vertex \( v \) to \( v' \), the continuous state of the system and the control input should belong to \( \text{Guard}(v, v') \). For instance, in Figure 6, when the system is in mode \( \text{vc} \), the control input \( \text{cmd}_P \) can cause a transition to the mode \( \text{pc} \). In the guard map for this transition, no condition has been considered on the continuous state of the system, and only the discrete control input is used for the guard condition.

- \( \text{Reset}_R : E_R \times X_R \times U_R \rightarrow 2^{X_R} \) describes the reset map. For instance, \( z' \in \text{Reset}(v, v', z, w) \) shows that for \( (v, v') \in E_R, z \in X_R, \) and \( w \in U_R \), there is a transition for which the continuous state of the system will be reset to \( z' \). Here, the reset map is an identity map as there is no jump on the continuous state of the system. When the reset map is an identity map, it is not shown in the graph representation.

- \( h_R : V_R \times X_R \rightarrow Y_R \) is the output map. Here we have \( h(v, x) = x_{\text{out}} \).

### 3.3 Motion planning layer

Based on the feedbacked information received from the regulation layer, the motion planning layer can activate the corresponding control mode in the regulation layer and can generate proper control references in the form of a feasible path to be tracked by the regulation layer. The path generation mechanism could be done in an offline manner or through a dynamic path planning mechanism.

#### 3.3.1 Offline path generation mechanism

In this method, based on the problem requirements, a proper path can be generated and stored in the library of the system. As an example, we explain a motion planning layer that has been used in our flight tests using the offline path generation mechanism. The hybrid automaton for this model of the motion planning layer is \( H_p = (V_p, X_p, U_p, Y_p, \text{start}, \text{pc}, \text{Reset}_p, h_p) \) where \( X_p = (r_x, r_y, r_z, r_P) \) is the continuous state of the motion planning layer and, instead, it is the generated reference that is going to be given to the regulation layer. The discrete state is \( V_p = \{ \text{start}, \text{PathC}_p, \text{PathZ}_p, \text{Ascend}_p, \text{Descend}_p, \text{Hover}_p, \text{Vel}_p \} \) and \( P_{\text{cmd}} \) start for starting the task, zigzag path tracking, circle path tracking, ascending, hovering, generating velocity references, descending, and emergency mode, respectively. Here, the control signal is \( U_p = U_{C_p} \times U_{D_p} \) where \( U_{C_p} = X_p \) is the current state of the system that is feedbacked from the regulation layer and \( U_{D_p} = \{ \text{cmd}_{\text{PathC}}, \text{cmd}_{\text{Descend}}, \text{cmd}_{\text{Hover}}, \text{cmd}_{\text{Vel}}, \text{cmd}_{\text{Ascend}}, \text{cmd}_{\text{emergency}} \} \) is the command received from the supervision layer. When the motion planning layer receives one of these commands, it switches to the corresponding discrete mode. \( Y_p = Y_{D_p} \times X_{C_p} \) is the layer output. Here, \( Y_{C_p} = X_p \) is the continuous part, which informs the supervision layer about the current state of the motion planning layer and also, it will be given to the regulation layer as the generated reference to be tracked. \( Y_{D_p} = Y_{D_p} \times X_{D_p} \) is the discrete output signal where \( Y_{D_p} + V_p \) is given to the supervisor to inform about the current discrete mode of the motion planning layer, and \( Y_{D_p} = \{ \text{cmd}_p, \text{cmd}_i \} \) is the command that activates a proper control mode in the regulation layer:

\[
Y_{D_p} = \{ \text{cmd}_p \text{ for } V_p = \text{PathC}_p, \text{PathZ}_p, \text{Ascend}_p, \text{Descend}_p, \text{cmd}_i \text{ for } V_p = \text{Vel}_p, \text{Emergency}_p, \text{Hover}_p \}
\]

The dynamics of the motion planning layer is

\[
\dot{X}_p(v) = [\dot{x}_r, \dot{y}_r, \dot{z}_r, \dot{\psi}_r] = \begin{cases} (0, 0, f_{x_r}(t), 0) & v = \text{Ascend}_p, f_{x_r}(t) > 0 \\
(0, 0, f_{x_r}(t), 0) & v = \text{Descend}_p, f_{x_r}(t) < 0 \\
(f_{x_r}(t), f_{y_r}(t), f_{z_r}(t), f_{\psi_r}(t)) & v = \text{PathC}_p \\
(f_{x_r}(t), f_{y_r}(t), f_{z_r}(t), f_{\psi_r}(t)) & v = \text{PathZ}_p \\
(f_{x_r}(t), f_{y_r}(t), f_{z_r}(t), f_{\psi_r}(t)) & v = \text{Vel}_p \\
(0, 0, 0, 0) & v = \text{Emergency}_p, \text{Hover}_p
\end{cases}
\]

In the graph representation for the hybrid model of the motion planning layer, all discrete states are connected, and the command \( \text{cmd}_s \) can fire a transition to the state \( * \). There
is no guard condition and jump for the discrete transitions. As this graph is tedious, we have not shown it here.

3.3.2 Online path generation mechanism

Here, the objective is to generate the references in an online way to be tracked by the regulation layer. The basic path planning problem in which a robot have to be driven from the start point towards the destination point while respecting the constraints, is a standard optimal control problem and has been addressed with different methods such as potential function, MILP, cell decompositions, and probabilistic road maps (Latombe, 1990). But, these methods are not able to address more advance path planning problems when there are number of goals with a particular order of execution. The alternative solution is to utilise symbolic motion planning approaches (Belta et al., 2007; Karimoddini & Lin, 2013) by which it is possible to generate a path associated with a sequence of symbols, which can follow logical supervisory rules. For this purpose, one can introduce an abstract system \( \dot{x}_p(t) = f_p(x_p(t), u_p(t)) \), which is simpler than the original model of the regulation layer as it ignores some unnecessary information. This abstract system should be approximately similar to the regulation layer dynamics so that the regulation layer can follow the generated reference. To elaborate the idea, let us work on the design of the motion planning layer for one of the NUS UAV helicopters that is involved in a leader–follower formation mission as a follower. As we explained, for the regulation layer of this helicopter, we have used a multi-layer control structure whose inner-loop controller stabilises the system using \( H_\infty \) control design techniques and its outer loop is used to drive the system towards the desired position (Figure 7). Assuming that the inner loop is fast enough to track the given references (Karimoddini, Cai, Chen, Lin, & Lee, 2011), the inner loop can be approximated by an identity matrix. Therefore, the regulation layer dynamics is approximately \( \dot{x}_p = u_p \), where \( x_p \) is the outer-loop state variable, and \( u_p \) is a control parameter, which should be designed by the formation algorithm.

Considering the follower velocity in the form of \( V_{\text{follower}} = V_{\text{leader}} + V_{\text{rel}} \), we can imagine a relative coordinate system in which the leader has a relatively fixed position and hence, the formation problem is reduced to drive the follower UAV towards the desired position. For this purpose, in Karimoddini, Lin, Chen, and Lee (2013), we have introduced a hybrid symbolic approach based on spherically partitioning of the space. Consider a sphere \( S_{R_m} \) with the radius of \( R_m \) that is centred at the desired position. The sphere is partitioned into several sectors as shown in Figure 8. To reach the formation, the system’s trajectory should reach one of the sectors adjacent to the sphere’s origin, and to maintain the formation, the system trajectory should remain there forever. Meanwhile, the follower UAV should avoid the collision with the leader UAV. These tasks can be achieved by properly driving the system trajectory through the partitioned space. Since the motion planning dynamics have a linear form, the control \( u_p \) can be constructed as the convex combinations of control signals on the vertices, so that the system trajectory either remain inside one of the sectors or exit from a desired facet. The resulting control signal is in the form of \( u_p(cmd) = \sum_{v_m} \lambda_m u_{v_m}(cmd) \), \( m = 0, 1, \ldots, 7 \), where \( 0 \leq \lambda_m \leq 1 \) are coefficients, \( u_{v_m}(cmd) \) are the control values at the vertices, and \( cmd \) is the discrete command, which could be cmd_H.

Figure 7. Control structure of the UAV.

Figure 8. A spherically partitioned space.
The hybrid model for the motion planning layer for a formation mission is shown in Figure 9. The subscripts \( cmd_K \), or \( cmd_C \) that stand for the commands for reaching the formation, keeping the formation, and collision avoidance, respectively. Further details about this online path generation mechanism are available in Karimoddini et al. (2013). Using this method, the hybrid model for the motion planning layer of the follower unmanned helicopter is \( H_P = (V_P, X_P, U_P, Y_P, f_P, \text{Init}_P, \text{Inv}_P, E_P, \text{Guard}_P, \text{Reset}_P, h_P) \), where \( X_P = (x, \dot{x}, y, \dot{y}, z, \dot{z}) \) is the continuous state of the motion planning layer. The discrete state is \( V_P = \{ \text{Start}_P, \text{Hover}_P, \text{ReachF ormation}_P, \text{KeepF ormation}_P, \text{CollisionAvoidance}_P \} \). Similar to the previous case, the control signal is \( U_P = U_{C_p} \times U_{D_p} \) where \( U_{C_p} = X_R \), and \( U_{D_p} = U_{D_p} \times U_{D_p} \). The set \( U_{D_p} = \{ cmd_H, cmd_R, cmd_K, cmd_C \} \) is the command received from the supervision layer, and \( U_{D_p} \) is the the information about the current discrete mode of the regulation layer. The subscripts \( R, K, C, \) and \( H \) stand for reaching the formation, keeping the formation, collision avoidance, and hovering, respectively. The output is \( Y_P = Y_{D_p} \times Y_{C_p} \), where \( Y_{C_p} = X_R \) is the continuous part and \( Y_{D_p} = Y_{D_p} \times Y_{D_p} \) is the discrete output signal where \( Y_{D_p} = V_P \) is the discrete output to be given to the supervisor to inform about the current discrete mode of the motion planning layer, and \( Y_{D_p} = \{ cmd_D, cmd_C \} \) is the command that activates a proper control mode in the regulation layer:

\[
Y_{D_p} = \begin{cases} 
    cmd_D & \text{for } V_P = \text{Hover}_P \\
    cmd_C & \text{for } V_P = \text{ReachF ormation}_P, \\
    \text{KeepF ormation}_P, \text{CollisionAvoidance}_P. & 
\end{cases}
\]

The dynamics of the motion planning layer is as follows:

\[
\dot{x}_p = [\dot{x}, \dot{y}, \dot{z}]^T = \begin{cases} 
    \sum_{m=0}^{7} \lambda_m u_m (cmd_R) & \text{for } m = 0, 1, \ldots, 7, \\
    \sum_{m=0}^{7} \lambda_m u_m (cmd_K) & \text{for } m = 0, 1, \ldots, 7, \\
    \sum_{m=0}^{7} \lambda_m u_m (cmd_C) & \text{for } m = 0, 1, \ldots, 7, \\
    0 & \text{for } v = \text{Hover}_P. 
\end{cases}
\]

The transitions for this hybrid model are shown in the graph representation of the system in Figure 9.

### 3.4 Supervision layer

This layer is responsible for the decision-making and task scheduling for the mission that should be performed by the UAV. The supervision layer can be presented by a purely discrete automaton (Ramadge & Wonham, 1989) or a timed automaton (Alur & Dill, 1994), which are subclasses of hybrid systems. Using the offline path planning mechanism for the motion planning layer, described in the previous section, a supervision layer has been designed for a typical mission shown in Figure 10. This mission starts with 8 m ascending, followed by 15 s hovering, 60 s zigzag path tracking, 35 s velocity control, 42 s circle path tracking, 20 s hovering, and 8 m descending. The mission ends with hovering. For safety issues, when the measured
signals are out of range, the fuel level sensor alarms or other possible problems occur, a fault signal is generated, which leads the system to the emergency mode. The discrete states and corresponding discrete outputs are shown in Figure 10. These discrete outputs are commands that activate a control mode in the motion planning layer. The input space of this layer is in the form of
\[ U_s = U_{Cs} \times U_{Ds} \]
where
\[ U_{Cs} = Y_{Cs} = X_{Ps} \]
is the current state of the path planner, and
\[ U_{Ds} = U_{Dse} \times U_{Dsp} \]
is the information about the current discrete mode of the motion planning layer, and
\[ U_{Dps} = \{ cmd_{StartMission}, Fault \} \]
is the external events generated by the other sources. Here, the command \( cmd_{StartMission} \) is generated by the ground station, and the command \( Fault \) is generated by the UAV event generation mechanism for faulty cases (e.g., when the measurement values are out of range).

As another example, using the motion planning layer for the online path planning, a supervisor has been designed for a follower UAV involved in a formation mission as shown in Figure 11. It starts with the hovering. When the follower receives the event \( cmd_{StartFormation} \) from the leader, it switches to the \( ReachFormation \) mode. If the supervisor detects a collision alarm, an event \( cmd_{CollisionAlarm} \) will be generated and the system switches to the \( CollisionAvoidance \) mode. Disappearing the collision alarm, the command \( cmd_{AlarmRemoved} \) causes a transition to the \( ReachFormation \) mode to resume the formation. Finally, when the formation is achieved, the system switches to the \( KeepFormation \) mode. The input space for this supervisor is in the form of
\[ U_s = U_{Cs} \times U_{Ds} \]
where
\[ U_{Cs} = Y_{Cs} = X_{Ps} \]
is the current state of the path planner, and
\[ U_{Ds} = U_{Dse} \times U_{Dsp} \]
is the output of received from the motion planning layer, \[ U_{Dps} = \{ cmd_{CollisionAlarm}, cmd_{AlarmRemoved}, cmd_{CollisionDetection} \} \]
is the set of events received from the motion planning layer, \[ U_{Dps} = \{ cmd_{StartMission}, cmd_{StartFormation}, cmd_{EndFormation} \} \]
is the set of events observed by the supervisor, and
\[ U_{Dse} = \{ cmd_{StartMission}, cmd_{StartFormation}, cmd_{EndFormation} \} \]
is the set of external events received from other sources such as the ground station or the leader UAV. The output is in the form of
\[ Y_s = Y_{Ds} = \{ cmd_R, cmd_K, cmd_C, cmd_H, cmd_E \} \]
These commands activate a proper control mode in the motion planning layer. The transitions and other details can be seen in Figure 11.

### 3.5 Synchronising the layers of the control hierarchy

To establish such a hierarchy, it is required to introduce a composition operator to synchronise the layers of the control hierarchy and to capture their relation (Karimoddini et al., 2011). In Johansson (2005), a definition of parallel composition for fully connected hybrid systems is introduced. The resulting closed-loop system for such a system is an autonomous unit which cannot be extended to a multi-agent scenario or a multi-layer structure. In Lynch
et al. (2001) and Rashid and Lygeros (1999), a more general definition of composition of hybrid systems has been given in which the components need not to be fully connected. However, in this method, the elements only coexist in the combined system and there is no refinement on the transitions and states of the closed-loop system. In contrast, here, a new definition of the composition operator is given for hybrid systems that can be used for hybrid multi-agent systems or a multi-layer hybrid system. Furthermore, it considers a treatment on the discrete transitions and states of the composed system, which leads to a more simplified system. First, we need to define the composability condition.

**Definition 3.1: Composability of hybrid automata**

Hybrid automata $H_1, H_2, \ldots, H_n$ are composable, if

1. $Y_i \cap Y_j = \emptyset$, $V_i \cap V_j = \emptyset$, $X_i \cap X_j = \emptyset$ for all $i \neq j$ and $i,j = 1, \ldots, n$,
2. $U_i \setminus Y_i = \emptyset$ for all $i = 1, \ldots, n$.

The first condition avoids the conflict between the components and the second condition guarantees the causality condition.

**Definition 3.2: Composition of hybrid automata**

Consider two composable hybrid automata $H_1 = (V_1, X_1, U_1, Y_1, f_1, \text{Init}_1, \text{Inv}_1, \text{Guard}_1, \text{Reset}_1, h_1)$ and $H_2 = (V_2, X_2, U_2, Y_2, f_2, \text{Init}_2, \text{Inv}_2, \text{Guard}_2, \text{Reset}_2, h_2)$. The composition of $H_1$ and $H_2$, denoted by $H_1 \parallel H_2$, is the automaton $H = (V, X, U, Y, f, \text{Init}, \text{Inv}, \text{Guard}, \text{Reset}, h)$, where

- $V = V_1 \times V_2$ and $X = X_1 \times X_2$;
- $U = (U_1 \setminus Y_2) \times (U_2 \setminus Y_1)$ and $Y = Y_1 \times Y_2$ (see Figure 12);
- $h : V \times X \rightarrow Y$, where $h = \begin{bmatrix} h_1 : V_1 \times X_1 \rightarrow Y_1 \\ h_2 : V_2 \times X_2 \rightarrow Y_2 \end{bmatrix}$.

![Figure 11. The supervision layer for a formation mission.](image)

![Figure 12. Input and output channels.](image)

![Figure 13. The layers of the control hierarchy.](image)
Figure 14. The composed system for the formation mission.

- **Init** = \{((v_1, v_2), (x_1, x_2))(v_1, x_1) \in Init_1 \land (v_2, x_2) \in Init_2\};
- **Inv** = \{((v_1, v_2), (x_1, x_2), (u_{11}, u_{22})) \exists u_1, u_2 s.t. (v_1, x_1, u_1) \in Inv_1, (v_2, x_2, u_2) \in Inv_2, u_1 = (u_{11}, u_{12}), u_2 = (u_{22}, u_{21}), u_{11} = u_1 \cap v_1, u_{22} = u_2 \cap v_2, u_{12} = u_1 \cap u_{21} = h_{21}(v_2, x_2), u_{21} = u_2 \cap y_1 = h_{12}(v_1, x_1)\};
- **E** = \{e = ((v_1, v_2), (v'_1, v'_2)) \in V \times V|\ (v_1, v'_1) \in E_1 and (v_2, v'_2) \in E_2 and Guard(e) \neq \emptyset\};
- **Guard**: \( E \rightarrow 2^X \times U \), which can be described as \( Guard((v_1, v'_1), (v_2, v'_2)) = ((x_1, x_2), (u_{11}, u_{22})) \in X \times U|((v_1, v_2), (u_{11}, u_{22})) \in E_1, (v'_1, v'_2) \in E_2, \exists u_1, u_2 s.t. (x_1, u_1) \in G_1(v_1, v'_1), (x_2, u_2) \in G_2(v_2, v'_2), u_{11} = u_1 \cap y_1, u_{22} = u_2 \cap y_1, u_{12} = u_1 \cap u_{21} = h_{21}(v_2, x_2), u_{21} = u_2 \cap y_1 = h_{12}(v_1, x_1)\};
- **Reset**: \( E \times X \times U \rightarrow 2^X \) where for the composed system is defined as \( Reset(((v_1, v_2), (v'_1, v'_2)), (x_1, x_2), (u_{11}, u_{22})) = ((x'_1, x'_2) \in X|\exists u_1 = (u_{11}, u_{12}), u_2 = (u_{22}, u_{21}) s.t. ((x_1, x_2), (u_{11}, u_{22})) \in G((v_1, v_2), (v'_1, v'_2)), x'_1 \in Reset_1((v_1, v'_1), x_1, u_1), x'_2 \in Reset_2((v_2, v'_2), x_2, u_2), u_{11} = u_1 \land y_2, u_{22} = u_2 \cap y_1, u_{12} = u_1 \cap y_2 = h_{21}(v_2, x_2), u_{21} = u_2 \cap y_1 = h_{12}(v_1, x_1)\)).

The control hierarchy of the UAV and the data flow between the layers are shown in Figure 13. Using the hybrid composition operator, the layers of this hierarchy can be synchronised. Furthermore, using this composition operator, the closed-loop system can be achieved. For instance, the regulation layer with the motion planning
layer for the online path planning, and the supervision for the formation control have been composed and the result is shown in Figure 14. This composed system gives an insight into the closed-loop system for this controlled system. Also, since most of the hybrid tools are developed for a single-layer hybrid system, for this composed hybrid model of the system, we can apply hybrid analysis tools such as model checking (Henzinger, Ho, & Wong-Toi, 1997) and verification (Alur, Courcoubetis, Henzinger, & Ho, 1993).

4. Implementation and experimental results
The proposed control structure is implemented in the avionic system of this NUS UAV and several flight tests have been conducted to evaluate this control hierarchy.
First, the supervision layer for the offline path generation (Figure 10) together with the motion planning layer discussed in Section 3.3.1 have been used to conduct a flight test. The assigned mission in this experiment is composed of several successive tasks. It starts with 8 m ascending, followed by hovering, zigzag path tracking, velocity control, circle path tracking, hovering, and 8 m descending. The mission ends with hovering. The state variables of the UAV are shown in Figure 15. The control signals recorded in the flight test are shown in Figure 16. To have a better sense of the system performance, the reference signals and actual flight test data in zigzag path tracking, velocity control, and circle path tracking modes are presented in Figure 17. As it can be seen in this figure, the system is able to follow the given trajectory. Small deviations from the reference path could be due to the wind disturbances (around 2–3 m/s in the horizontal plane) and GPS signal errors as the position accuracy of GPS is 3 m circular error probability (CEP). The video of this flight test is available at http://www.youtube.com/watch?v=NRbRkeZVrpQ.

In the second experiment, we have implemented this control hierarchy in the avionic system of a follower UAV which is involved in a formation mission. For this experiment, we have used the supervision layer and the motion planning layer shown in Figures 9 and 11, respectively. In this experiment, the leader follows a line path and the follower should reach and keep the formation. The follower is initially located at a point that has a relative distance of \((dx, dy) = (-17.8, 11.4)\) with respect to the desired position. Starting form a hovering mode, then the leader issues the start command, and after 17 s, the follower reaches the formation that has a relative distance of \((dx, dy) = (-5, -15)\) with respect to the leader (Figure 18(a)). The position of both follower UAV and the leader UAV are shown in Figure 18(b). The video of this flight test is available at http://www.youtube.com/watch?v=Aji7rs-zUjQ.
5. Conclusion
In this paper, we developed a hierarchical hybrid control structure for a UAV helicopter. This hierarchy consists of three layers: the regulation layer, which is responsible for reference tracking; the motion planning layer, which is responsible for the path planning; and the supervision layer, which is responsible for the task scheduling and decision-making. Each layer was modelled by an input/output hybrid automaton and the discrete transitions and continuous dynamics of the system were simultaneously captured within the hybrid framework. Then, a composed hybrid operation was proposed to synchronise the layers of the control hierarchy and to obtain the whole closed-loop system. With this control scheme, two experiments were done to verify the proposed approach. In the first experiment, the UAV was involved in a mission composed of several successive tasks, and in the second flight test, the UAV was involved in a formation mission as a follower UAV. Both scenarios were successfully implemented and the actual flight tests showed the effectiveness of the control structure. As our future research direction, further properties of the proposed hierarchical hybrid control structure such as the stability of the overall system will be studied.
